ABSTRACT

System design is an important phase of system engineering, determining system architecture to satisfy specific requirements. System design focuses on analyzing performance requirements, system modeling and prototyping, defining and optimizing system architecture, and studying system design tradeoffs and risks. Modern enterprise information systems (EIS) are distributed systems usually built on multitiered client server architectures, which can be modeled using well-known frameworks, such as Zachman enterprise architecture or open distributed processing reference model (RM-ODP). Both frameworks identify different system models, named views, corresponding to discrete stakeholder’s perspectives, specific viewpoints, and could serve as a basis for model-based system design. The main focus of this chapter is to explore the potential of model-based design for enterprise information systems (EIS). To this end, the basic requirements for model-based EIS design are identified, while three alternative approaches are discussed based on the above requirements, namely, rational unified process for systems engineering (RUP SE), UML4ODP and EIS design framework.

INTRODUCTION

Many different stakeholders are usually involved in the process of constructing an enterprise information system. Each of them focuses on certain concerns and considers these concerns at a certain level of detail. Therefore, various methodologies and frameworks have been developed aiming at the consistent construction of enterprise information systems. Most of them have adopted the notion of separating concerns by establishing different viewpoints, each depicting the concerns of a specific
Frameworks for Model-Based Design of Enterprise Information Systems

stakeholder (e.g., user, designer, implementer, etc.). Following, we focus on the system designer viewpoint, exploring issues related to the analysis and design of enterprise information systems (EIS).

System design is the process of analyzing system requirements, designing the desired architecture of a system, and exploring performance requirements, ensuring, thus, that all system components are identified and properly allocated and that system resources can provide the desired performance. System design is a phase of system engineering, defined by the International Council on System Engineering (INCOSE) as “the interdisciplinary approach and means to enable the realization of successful systems” (INCOSE, 1998). System engineering covers different phases, as the definition of customer needs and required functionality early in the development cycle, the documentation of requirements, the design synthesis, and system validation, while the overall system life cycle, performance, and even maintenance is also considered (Oliver, Kellher, & Keegan, 1997).

System design corresponds to the system designer viewpoint. Although, vendors (as IBM or Oracle) actively promote information system development based on multitiered architectures, the proposed solutions, although expensive, often fail to provide the desired performance. This is due to the fact that system designers often neglect engineering issues contributing to the overall system performance. In practice, discrete issues, as network architecture description or resource allocation, are supported by autonomous automated or semiautomated tools, each of which adopts its own metamodel for system representation. Thus, no interaction between them is supported. To effectively explore EIS design, heterogeneous tools and system models should be integrated. This integration could be accomplished by adopting model-based system design (MBSD). MBSD provides a central system model (tool-independent) that captures system requirements and design decisions that fulfill them at different levels of abstraction. It enables integration of system models supported by autonomous design tools and interoperability between them without interfering with their internal implementation. When applying model-based system design, a multilevel, technology-neutral model for EIS representation should be defined, taking into account different aspects of the system, such as network architecture, resource allocation, application execution requirements, and so forth, involved in system design.

Existing well-known frameworks may be used for system modeling. The open distributed processing reference model (RM-ODP) is such a framework, dealing with aspects related to the distribution, interoperation, and portability of distributed information systems. Another widely referenced framework is the enterprise architecture framework defined by Zachman, which specifies the development process of enterprise information systems, starting from the identification of the enterprise’s business objectives and resulting in a detailed system implementation. Independently of the framework used, the different system views defined from each viewpoint should be represented by graphical models enhancing the designer perspective of the system. Graphical models may be expressed using various modeling languages. However, the most popular and widely adopted modeling language is the unified modeling language (UML). System designers commonly use the extension mechanisms provided by UML to create profiles (i.e., specializations of UML diagrams) to better serve their modeling purposes.

The main focus of this chapter is to explore the potential of model-based design for enterprise information systems. To this end, the basic requirements for model-based EIS design are identified, while three alternative approaches are discussed based on the above requirements. Although they are not the only ones, they were chosen since they focus on system design, provide formal EIS models, and adopt UML as the modeling language for EIS representation. These are: a) the rational unified process (RUP) system engineering approach, b) the UML for open distributed processing (UML4ODP) proposed standard with emphasis on engineering viewpoint, and c) the EIS engineering framework proposed by the authors.
Frameworks for Model-Based Design of Enterprise Information Systems

The rest of the chapter is organized as follows: In second section, background information regarding model-based system design and system viewpoints is provided. Also, the Zachman framework and RM-ODP are briefly presented and their relevance to the proposed approach is discussed. In the next section, the requirements for successful model-based design for enterprise information systems are presented. In the following sections, the three alternative approaches are analyzed and discussed based on these requirements. Future trends and conclusions reside in the last two sections.

BACKGROUND

This section describes the main principles of model-based system design (MBSD) and its advantages for enterprise information systems. System modeling is a critical issue in MBSD. The IEEE Std 1471, which provides guidelines for the description of systems from different perspectives (viewpoints), is considered as the basis for the definition of a central system model for MBSD. An overview of existing frameworks for enterprise architecture description is discussed by Goethals, Lemahieu, Snoeck, and Vandenbulcke (2006) and Leist and Zellner (2006). We discuss two of them, namely the Zachman framework and RM-ODP, since they support the designer perspective and can be used as a basis for EIS modeling. They are well-known and come from different origins. It should be noted that although defined prior to IEEE 1471 standard, they both adopt the concepts of views and viewpoints.

Model-Based System Design

System modeling constitutes an important part of system design, since it may facilitate the complete description of all aspects involved and contribute to the effectiveness of the whole process. How many different system models should be supported? Should all of them provide the same level of detail? How can the correspondences between different models be identified and ensured? Since discrete design issues are usually resolved by different methodologies and autonomous software tools, the support of different system models cannot be avoided. In many cases, these models are not compatible, thus, design issues, although interrelated, are often solved in isolation. Even if a certain design problem, for example, a network architecture, is optimized, there is no guarantee that the overall EIS architecture will be optimized as well. To resolve such a situation, a central, tool-independent model should be adopted.

Model-driven technologies for application development, such as model driven architecture (MDA) (Brown, 2004), proposed by Object Management Group (OMG), enable the definition of platform-independent models (PIMs) for the specification of system functionalities and platform-specific models (PSMs) for the specification of the implementation of these functionalities on a particular technological platform and the definition of couplings between PIMs and PSMs. Modeling languages, methods and tools have been established to support model-driven software development. In a similar fashion, model-based system design (MBSD) provides a central system model (corresponding to a PIM) that captures, at different levels of abstraction, system requirements and design decisions that fulfill them. In addition, tool-specific models could be defined (corresponding to PSMs), while MBSD also provides for model transformation (couplings between PIM and PSMs). Thus, the interoperability between models and methods corresponding to discrete design issues is achieved, without interfering with their internal implementation in the respective software tools. The central system model serves all design activities; for example, it could be executed by a simulator to validate design decisions.

The UML is a modeling language attempting to standardize graphical language elements for modeling software systems. It is a well-known software engineering standard, since most software developers are familiar with it, while there is a lot of activity in advancing both the UML supported
Frameworks for Model-Based Design of Enterprise Information Systems

functionality and the UML tools. Numerous designers use the extension mechanisms provided by UML to create profiles (i.e., specializations of UML diagrams) to better serve their modeling purposes. UML 2.0 (OMG, 2007) consists of 13 diagram types used for structural, behavioral, and interaction modeling. Many diagram types, such as use-case, state, and activity, can be used for general functional requirement analysis. Evidently, UML is adopted in MBSD as well, serving as a common enterprise notation language, while UML extensions have been proposed for system design (Murray, 2003a; Nikolaidou, Alexopoulou, Tsadimas, Dais, & Anagnostopoulos, 2006).

As it will be elucidated in this chapter, MBSD is appropriate for enterprise information system analysis and design. When applying MBSD, a multilevel, technology-neutral model for EIS representation should be defined, taking into account different aspects of the system, such as network architecture, resource allocation, application execution requirements, and so forth involved in system design. Existing modeling frameworks are explored for this purpose in the following paragraphs. Independently of the framework used, we suggest that UML should be adopted for model representation.

Defining Views and Viewpoints for Enterprise Information System Architecture

An important milestone in the field of enterprise system architecture descriptions is ANSI/IEEE Std 1471 - Recommended Practice for Architectural Description of Software-Intensive Systems (IEEE1471). It defines enterprise system concepts and their relationships that are relevant for architectural description, thus providing a standard way of defining EIS architecture models. It also provides guidance on the structure of architectural descriptions.

The main concepts standardized are architecture, architectural description, concern, stakeholder, viewpoint, and view. Architecture is defined as “the fundamental organization of a system embodied in its components, their relationships to each other, and to the environment, and the principles guiding its design and evolution.” Architecture description is “a collection of artifacts documenting the architecture.” Stakeholders are “people with key roles or concerns about the system,” while concerns are “the key interests crucially important to the stakeholders and determine the acceptability of the system from stakeholder specific perspective.” Views are “representations of the whole system from the perspective of a related set of concerns,” while viewpoints define “the perspective from which a view is taken.” The main concepts of IEEE 1471 standard and their interrelations are depicted in Figure 1.

A viewpoint defines: (a) how to construct and use a view; (b) the information that should appear in the view; (c) the modelling techniques for expressing and analyzing the information; and (d) a rationale for these choices (by describing the purpose and intended audience of the view). Different stakeholders with different roles in the system have different concerns, which are expressed through different viewpoints. Each view is a capture of the representation of the system architecture design, typically comprising of one or more architecture models. In simple words, a view is what you see, while a viewpoint is where you are looking from, that is, the vantage point or perspective which determines what you see. Viewpoints are generic, while a view is always specific to the architecture for which it is created. To successfully define an architecture description, specific characteristics should be obtained (Hilliard, 2001):

- Views should be modular. A view may consist of one or more architectural models.
- Views should be well-formed. Each view has an underlying viewpoint specifying view definition using a formal method, as languages, notations, models, and analytical techniques.
• View consistency should be ensured. Viewpoints may also include: a) any consistency or completeness checks associated with the underlying method to be applied to models within the view; b) any evaluation or analysis techniques to be applied to models within the view; and c) any heuristics, patterns, or other guidelines which aid in the synthesis of an associated view or its models.

Although not defined in IEEE 1471, additional issues should be addressed, such as (Hilliard, 2001):

• View integration and inter-view consistency. It has been long recognized that introducing multiple views into architectural descriptions leads to an integration problem. How does one keep views consistent and nonoverlapping? The introduction of viewpoint declarations, while not solving the problem, gives us a tool for detecting overlaps and inconsistencies, and potentially a substrate for solving the integration problem.

• Formalization. The conceptual framework of IEEE 1471 is an informal, qualitative model. If it is useful, which appears to be the case, it may be insightful to attempt to formalize the concepts therein. Such a formalization could have benefits in several topics, such as view checking, view integration, and inter-view analysis.

Since its publication in 2000, IEEE 1471 has received much appraisal. The concepts of stakeholders, concerns, and views are accepted as essential. The terminology proposed by IEEE 1471 is now being used by many architects. The focus on concerns of stakeholders is a good stimulus for otherwise possibly too technically-oriented IT architects. After all, it is the interests of the stakeholders that need to be served.

IEEE 1471 proposes a formal method to define system architectures, but it does not propose nor prescribe any specific viewpoint for system architects and stakeholders (Greefhorst, Koning, & Hans van, 2006). However, it can be used as a guide to define viewpoints and views for EIS model-based analysis and design, as discussed in the follow-
Frameworks for Model-Based Design of Enterprise Information Systems

...ing sections. Inter-view consistency and formal description is the focus of our concern. As already mentioned, each view may be formally defined by a model, while it should also be communicated to the stakeholder by a representation model, which is a concrete representation of the system view on some medium (e.g., paper or computer program) (Boer, Bonsangue, Jacob, Stam, & Torre, 2004). The aforementioned definitions are adopted throughout the rest of the chapter.

The attainment of a consistent representation of the systems entails that view interrelations must be typically defined. In order to formally define a viewpoint, one should define a metamodel describing the supported views independently of the modeling language used for system representation and then define the representation model. In this way, a view may be represented using different languages, such as UML, in a common manner, facilitating thus the transformation between representation modeling languages. As indicated by Dijkman, Quartel, Pires, and Sinderen (2003), two basic relations are identified between views: refinement (the internal view refines the external view on a different level of detail) and complement (two views may complement each other by considering complementary concerns).

**Zachman Framework**

Enterprise information systems can be described based on the Zachman framework. The widely referenced enterprise architecture framework of Zachman (1999), simply referred as the Zachman framework is a logical structure for organizing and classifying the artifacts created during the development of enterprise information systems. The purpose of the framework is to ensure the establishment of enterprise information systems starting from the identification of the enterprise’s business objectives. As a typical problem of modern enterprises is that in spite of time and money spent on the implementation of information systems, they often fail to meet business objectives.

The Zachman framework is deployed in two dimensions. The first dimension addresses the different perspectives of the stakeholders participating in information system development. These perspectives derive from the parallelism of information system development with the construction of a building. As such, Zachman defines the owner’s, designer’s, and builder’s viewpoints. The first viewpoint, defined by the business model, is a description of the enterprise within which the information system will function. The second delineates how the system will satisfy the requirements ensuing from the business objectives, yielding the system model. The third viewpoint represents how the system will be implemented, providing the builder model. To produce a comprehensive framework for enterprise information system development, Zachman has added three more viewpoints, namely scope, which denotes the business purpose and strategy defining the context for the other viewpoints, the out-of-context, which includes implementation-specific details, and the operational, which is the functioning system. The second dimension distinguishes different focal points of the system. The data aspect describes what entities are involved, while the function aspect shows how the entities are processed. The network perspective indicates where the entities are located. Apart from the what, how, and where, the framework addresses also three other questions, specifically who, when, and why. As such, it defines the people who work with the system, when events occur (time aspect), and why these activities take place (motivation aspect). The combination of the two dimensions in a matrix, with the focal points indicated by the columns and the different perspectives by the rows, yields the Zachman framework as presented in Figure 2.

Each cell constitutes a separate view. As such, an organization should create a wide range of diagrams and documents representing the different views defined within the Zachman framework. As shown in Figure 2, the Zachman framework contains suggested specification models for each view (e.g., using ER technique for modeling the...
data description in the owner’s viewpoint or using functional flow diagrams for modeling the process description in the owner’s viewpoint). However, it does not suggest a specific methodology or technique for the description of view models. Moreover it does not typically define a metamodel to integrate the information of all cells nor does it describe a way to trace information between cells (Frankel, Harmon, & Mukerji, 2003). Its objective is to provide some basic principles that should guide the implementation of enterprise information systems. As such, it says nothing about the development of conformant views or the order that should be developed. The strength of the framework is that it provides an organized way of thinking about an enterprise, in respect to information systems. It enables the individuals involved in producing enterprise information systems to focus on selected aspects of the system without losing sight of the overall enterprise context. Moreover, it facilitates them to find out possible gaps and inconsistencies between view representations and thus modify the models appropriately to eliminate all inconsistencies.

EIS design issues are obviously addressed in the system model raw of Zachman’s matrix. The system designer may actually work concurrently with the system developer (the builder of the model), although system design is usually performed prior to its implementation. As already stated, the Zachman framework does not specify whether these two stages must be performed sequentially or in parallel. In many cases, during system design, although system architecture is defined and the services provided by the distributed applications are identified, detail software design and implementation is considered in the builder model. In practice, system engineering issues can be dealt with independently of the status of software development process. Thus, following we will focus on the system model raw of Zachman’s matrix.

Lastly, it should be noted that while a plethora of methodologies and formalisms exist, each applicable to some subset of cells, Zachman however encourages a single common language to describe the subject of all the cells as well as their interrelationships, rather than using a specialized notation for each view separately (Sowa & Zachman, 1992).

Figure 2. Overview of the Zachman framework (Sowa & Zachman, 1992)
Open Distributed Processing Reference Model

As enterprise information systems are distributed, they can alternatively be described by the reference model of open distributed processing (RM-ODP). The RM-ODP is a conceptual framework established by ISO (ISO/IEC, 1998) for the specification of large-scale distributed systems. RM-ODP integrates aspects related to the distribution, inter-operation, and portability of distributed systems in such a way that network/hardware infrastructure is transparent to the user. RM-ODP manages system internal complexity through the separation of concerns, addressing specific problems dealt with during system development from different viewpoints (ISO/IEC, 1998). It provides an object-oriented representation of the system, while it is highly technical, relatively complex, and focuses on distributed application development. RM-ODP manages system internal complexity through the identification of five generic and complementary viewpoints, which are as follows:

- **Enterprise** viewpoint, which concentrates on the business activities of the specified system.
- **Information** viewpoint, which focuses on the information that needs to be stored and processed in the system.
- **Computational** viewpoint, which describes system functionality through functional decomposition of the system into components that interact via interfaces.
- **Engineering** viewpoint, which examines the mechanisms and functions required to support distributed interactions between components.
- **Technology** viewpoint, which focuses on the choice of technology for system implementation.

For each viewpoint there is an associated viewpoint language which can be used to express a specification of the system from that viewpoint. The object modeling concepts give a common basis for the viewpoint languages and make it possible to identify relationships between the different viewpoint specifications and to assert correspondences between the representations of the system in different viewpoints. Viewpoint languages provide the means for the detailed description of systems according to viewpoint perspective. System views are formally defined based on the corresponding viewpoint languages.

System design issues are addressed in RM-ODP **engineering viewpoint**. The engineering language focuses on the way system component interaction is achieved and on the resources needed to do so. In the engineering language, the main concern is the support of interactions between computational objects, defined in the computational view to represent a service or a program operating in the distributed platform. As a consequence, there are very direct links between the viewpoint descriptions; computational objects are visible in the engineering view as basic engineering objects (BEOs), representing the actual implementation of computational objects. Engineering objects are physically located and associated with processing resources by grouping them into nodes, which can be thought of as representing independently managed computing systems. A cluster is a grouping of basic engineering objects, used for resource allocation purposes (all objects in a cluster are manipulated as a single entity). Clusters form capsules (a single entity for the purpose of resource allocation and protection). Capsules are associated to nuclei which are responsible for making communications and processing facilities available (to capture the notion of a virtual machine). When engineering objects in different clusters interact, mechanisms are needed to cope with it. The set of mechanisms needed to do this constitute a channel (represents client-server communication), which is made up of a number of interacting engineering objects: Stubs are concerned with the information conveyed in an interaction; binders are concerned with maintaining
the association between the set of basic engineering objects linked by the channel; and protocol objects manage the actual communication. Basic engineering entities and their interrelations are depicted in Figure 3.

Although RM-ODP has been well-known since the late 90s, the concepts defined to describe system architecture (as clusters, capsules, or nuclei) in the engineering viewpoint are complex ones; while they are not adopted by system designers in their everyday work, they cannot be instantly related to them. Network architecture is described in great detail using client-server concepts, while the description of systems entities (e.g., communication channels) might be too detailed. Alternative architectural approaches should be easily described within engineering viewpoint to enhance its acceptance by system designers. Furthermore, the dependencies between viewpoints, although identified, are not formally enforced.

Regarding system design, within the engineering viewpoint the following aspects are clarified:

- A system-oriented view of distributed applications.
- System access points.
- The distributed platform infrastructure (e.g., network architecture and hardware configuration).
- The association of software components to network nodes (resource allocation) in order to ensure performance requirements.

However, the means of actually performing resource allocation are not provided, since performance requirements are not depicted within engineering viewpoint.

Frankel (2003) suggests separating the engineering viewpoint into two discrete subviewpoints, the logical and the deployment one. The deployment one focuses on a technology-independent description of the network architecture and hardware configuration. The logical one corresponds to the description of distributed application architecture and the policies adopted for the operation (e.g., replication policy). This separation helps in clarifying
the dependencies between application requirements and distributed platform infrastructure.

**MODEL-BASED EIS DESIGN**

Modern enterprise information systems are based on distributed architectures, consisting of a combination of Intranet and Internet Web-based applications. They are built on multitiered client-server models (Serain, 1999), as the J2EE architecture. Such platforms distinguish application logic from the user-interface and contribute to system configurability and extendibility. Despite the fact that vendors (such as IBM and Oracle) actively promote information system development using the aforementioned architectures, the proposed solutions, although expensive, often fail to provide the desired performance (Savino-Vázquez et al., 2000). This is due to the fact that design issues, although interrelated, are solved in isolation, while the internal complexity of applications is neglected when estimating the quality of service (QoS) imposed to the network supporting them.

In practice, discrete issues, as network architecture description or resource allocation, are supported by autonomous automated or semiautomated tools (Gomaa, Menasce, & Kerschberg, 1996; Graupner, Kotov, & Trinks, 2001; Nezlek, Hemant, & Nazareth, 1999). Each of these tools supports its own representation metamodel (e.g., queuing networks, Petri-nets, and objects), while different system properties are depicted in them. The existence of a common metamodel describing all EIS properties is of great importance for the efficient requirement analysis and design of such systems, since it would facilitate the communication between autonomous design stages/tools and act as a “reference point.” Thus, a model-based approach for EIS analysis and design is considered most efficient.

In order to provide an integrated framework for model-based enterprise information system design, the following requirements should be addressed:

- **Definition of a common, multilayered, platform-independent model of EIS architecture.** EIS architecture description should follow IEEE Std 1471, thus EIS model definition should consist of well defined views and viewpoints. Each view should address a discrete design issue and should be formally defined. Furthermore, view and inter-view consistency should be well-established, since the main reason for adopting model-based design is to ensure integration of discrete design issues/tools. Lastly, compatibility of the proposed model with Zachman system model or RM-ODP engineering viewpoint should also be explored to promote integration with other methodologies addressing system issues corresponding to complementary viewpoints.

- **Covering basic EIS architecture design issues** (as defined in both Zachman’s system model and RM-ODP engineering viewpoint). These are: a) definition of EIS architecture (e.g., a system-oriented view of distributed applications) indicating system performance requirements; b) definition of system access points; c) description of platform-independent distributed infrastructure (e.g., network architecture and hardware configuration); and d) mapping of software components to network nodes (resource allocation) in order to ensure performance requirements.

- **Description of a methodology for EIS architecture design.** This could be part of the viewpoints defined or independent of them. Thus, it could be applied at different levels of detail, facilitating the progressive definition of system architecture.

- **Definition of a UML representation model for EIS architecture.** It should provide for an integrated, easy-to-use interface for system designer.

- **Tool integration - Model exchangeability.** Since discrete design issues may be resolved using autonomous tools, heterogeneous tool integration should be supported. Most of
Frameworks for Model-Based Design of Enterprise Information Systems

them employ their own internal model for EIS representation. Thus, tool coordination and internal metamodel transformation should also be supported. According to model-based design principles, consistency is ensured, since the common metamodel acts as a “reference point.” Prior to using an existing tool, the partial transformation of the common metamodel (platform-independent) into the tool’s internal metamodel (platform-dependent) must be facilitated. Using this transformation, the invocation and initialization of any tool can be automatically performed. Input/output parameters must be represented in the common metamodel. Their values could be either entered by the system designer or automatically computed by the tool.

Following, we discuss three alternative approaches for model-based EIS design with regard to the above requirements. All of them adopt UML as the modeling language for EIS representation. These are: a) the RUP system engineering approach (Murray, 2003a, 2003b), b) the UML4ODP proposed standard with emphasis on engineering viewpoint (ISO/IEC, 2006), and c) EIS design framework proposed by the authors (Nikolaidou & Anagnostopoulos, 2005).

RUP SYSTEM ENGINEERING

Rational unified process for systems engineering (RUP SE) is a framework developed by Rational (Murray, 2003a) to address system design issues in conjunction with RUP methodology for software engineering. RUP SE adopts all the modeling concepts and perspectives of RUP and is fully compatible with it.

The purpose of RUP SE is to support teams of system engineers as they determine the black box view of the system (e.g., the system as a whole, that is, the services it provides and the requirements it meets) and specify an optimal white box system design (e.g., elements or parts that make up the system) that meets all stakeholder needs. In particular, RUP SE comprises:

1. An architecture framework, which describes the internals of a system (architectural elements) from multiple viewpoints;
2. A set of UML-based artifacts for system architecture modeling; and
3. A methodology, called use-case flowdown (Murray, 2003c), for deriving requirements for architectural elements.

RUP SE System Architecture Modeling Framework

The RUP SE system architecture framework is deployed in two dimensions (Brown & Densmore, 2005), as shown in Table 1. The first dimension defines a set of viewpoints that represent different areas of concern that must be addressed in the system architecture and design. Analytically, worker viewpoint expresses roles and responsibilities of system workers regarding the delivery of system services. Logical viewpoint concerns the logical decomposition of the system into a coherent set of UML subsystems that collaborate to provide the desired behavior. Physical viewpoint regards the physical decomposition of the system and specification of physical components. Information viewpoint focuses on the information stored and processed by the system. Process viewpoint examines the threads of control that carry out the computation elements. Lastly, geometric viewpoint denotes the spatial relationship between physical components.

In addition to viewpoints, building system architecture requires levels of specification as the architecture is being developed. There are four model levels defined in RUP SE, consistent to RUP. As shown in Table 1, these constitute the second dimension of the RUP SE architecture framework. The context level treats the entire system as a single entity, that is, a black box. It does not address the system’s internal elements. At the analysis level, the
Frameworks for Model-Based Design of Enterprise Information Systems

System's internal elements are defined (white box approach), describing domain elements at a relatively high level. These elements vary, depending on the specific viewpoint. For example, in the logical viewpoint, subsystems are defined to represent abstract, high-level elements of functionality. Less abstract elements are represented as sub-systems or classes. In the physical viewpoint, localities are defined to represent the places in which functionality is distributed. The design level is where design decisions that will drive the implementation are captured. The implementation level concerns decisions about technology choices for implementation. The intersection of model level rows with the viewpoint columns yields the different views of a system lifecycle. As shown in Table 1, each view comprises different model elements. It should be noted that RUP SE does not dictate that all system development efforts require every viewpoint. The introduced viewpoints are a mechanism to address different stakeholders' concerns but also to maintain an integrated, consistent representation of the overall system design.

One could identify a correspondence between RUP SE and Zachman's viewpoints, while we consider that context, analysis, and design model level could be incorporated within the system model row of Zachman's matrix. The context model level, in particular, may constitute the bridge to the upper Zachman row (business model) and the design model to the lower (technology model).

As presented in Figure 4, all system model aspects of the Zachman framework, except for the motivation which is not examined within RUP SE, are covered by the corresponding RUP SE viewpoints. RUP SE defines 18 different views corresponding to the system model row of the Zachman framework, which could be a bit confusing for the system designer. Furthermore, there is no formal definition of the models corresponding to each view (a formally defined metamodel), although the purpose and functionality of each of them is clearly defined, as stated in IEEE Std 1471.

### UML Representation Model

RUP SE employs UML 1.4 to create system artifacts for each view specified in the architecture framework. Each viewpoint is described using specific collaborating entities through context, analysis, and design levels. The use of UML for both object and relational database modeling is a well-developed practice that RUP SE makes use of in the information viewpoint, thus no stereotypes

Implementation Hardware and Software Configuration
were defined. The process viewpoint is represented as collaborating processes, using standard UML semantics (e.g., activity diagrams). The same is applied to geometric viewpoint as well, described as collaborating components (standard component diagrams).

Worker viewpoint mainly consists of worker diagrams, deriving from class diagrams containing worker and machine stereotypes. Logical viewpoint consists of context diagrams, used to depict logical decomposition of the system as a coherent set of UML subsystems that collaborate to provide the desired functionality. In UML 1.4, systems and subsystems inherit from classifiers and packages; there is no UML syntax that captures both the classifier and package aspects of a subsystem. In RUP and RUP SE, proxy classes are used to represent the classifier semantics. In RUP SE, systems/subsystems are stereotypes of proxy and package entities, while their distinct semantics are appropriately defined. A system context diagram captures a black box description of the system (Context level) and is further decomposed to its components in the system logical decomposition diagram (analysis level). Figure 5 presents as an example a RUP SE system context diagram for a retail system.

In the physical viewpoint, the system is decomposed into elements that host the logical subsystem services. Locality diagrams are the most abstract expression of this decomposition. They express where processing occurs without tying the processing locality to a specific geographic location, or even the realization of the processing capability to specific hardware. Locality refers to proximity of resources, not necessarily location, which is captured in the design model. The locality diagrams show the initial partitioning, how the system’s physical elements are distributed, and how they are connected. The term locality is used because locality of processing is often an issue when considering primarily nonfunctional requirements. Locality is defined as stereotype of a UML node element. Figure 6 presents a locality diagram that documents an engineering approach to a click-and-mortar enterprise that has a number of retail stores, central warehouse, and a Web presence. The rounded cube icon is used for the representation of the locality.

To support RUP SE, a RUP plug-in is provided for IBM rational tools. The currently available plug-in was released in June 2003 and can be used together with RUP v. 2003. It is based on UML 1.4, while in future versions RUP SE will move on to UML 2.0 semantics.

**Use-Case Flowdown Methodology for EIS Architecture Design**

Moving down model levels adds specificity to the models. As you move down the levels, each view is a more specific decision, resulting in configuration items at the implementation level. It is important to note that each model level realizes requirements discovered at a higher level. For example, physical viewpoint at the design level contains a descriptor node diagram, which shows a physical design that realizes each locality contained in the system locality diagram.

The context level treats the entire system as a single entity, thus the transition from the context to the analysis level is the process of adding detail.
Frameworks for Model-Based Design of Enterprise Information Systems

Figure 5. A system context diagram for a retail system (Murray, 2003b)

in the system model (black box to white box representation). In going from analysis to design, subsystems/classes and localities are transformed into hardware, software, and worker designs. This is not a direct mapping, since design decisions have to be made about how the functionality represented in the subsystems and classes will be allocated. Factored into these design decisions are considerations for supplementary requirements and distribution represented by the localities. The resulting design must realize all of the specifications from the analysis level. In other words, designing the system at the analysis level creates requirements that the design level must satisfy. Again, going from the design level to the implementation level is a transformation, but this time the mapping is more direct.

RUP SE use-case flowdown (Murray, 2003c) is the methodology used for the transition between model levels. Flowdown can be applied to add detail within a model level or to specify elements at a lower model level. For example, it can be used to determine system services at the context level, but similarly, it can be used at the analysis level to identify subsystem services and to break subsystems into further subsystems. Through use-case flowdown requirements may propagate from context to analysis and to design model levels. Use-case flowdown is applied recursively. Table 2 includes the steps of a simple flowdown for constructing system context diagram, as the one described in Figure 5, and identifying system services.

Flowdown steps may be applied as a joint realization analyzing the way the elements of multiple viewpoints collaborate in carrying out a service. The generic procedure of joint realization flowdown for context model level is presented in Table 3.

Discussion

The plethora of views all referring to the system model, although providing the capability of detail system description, are complex to manage. The most important issue is that they should be kept aligned and consistent with respect to each other. The design activity must ensure that these views can be related to each other, either directly or
indirectly, and to the information system as well. Thus, in order to ensure consistency and avoid the loss of critical information during system design, various types of relations between different views (and corresponding models) should be enforced (e.g., equivalence or refinement relations). To this end, the formal definition of a metamodel describing views lacking in RUP SE is very important.

RUP SE addresses all issues related to EIS design, utilizing the six viewpoints defined. Furthermore, different levels of detail are supported though model levels. Although the use-case flowdown methodology is concrete, it is a complex process, which can not be easily automated. The integration of specific tools for system design is also not mentioned.

UML 1.4 diagrams are employed for the illustration of proposed views. The RUP SE framework defines appropriate stereotypes for the views and a plug-in is provided for UML 1.4. UML 2.0 will be supported in a later version.

RUP SE is best suited for EIS that are large enough to obtain internal complexity, have concurrent hardware and software development, obtain architecturally significant deployment issues, and include a redesign of the underlying information

UML4ODP

UML4ODP is a standard developed by ISO (ISO/IEC, 2006), which further refines the ODP systems by using UML for the expression of ODP system specification in terms of RM-ODP viewpoint specifications. Using UML concepts, as well as the lightweight extension mechanism supported by UML, it provides:

1. A set of UML 2.0 profiles (one for each RM-ODP viewpoint) and the a way to use these profiles;
2. A profile for correspondences between viewpoints; and
3. A profile for conformance of implementations to specifications.

UML4ODP is also concerned about the relationships between RM-ODP viewpoint specifications and model-driven architectures such as MDA. UML notation contributes to RM-ODP's acceptance and promotes its usage by system designers. The engineering profile of UML4ODP expresses the concepts specified in the RM-ODP engineering viewpoint and conforms to engineering language.

Engineering Viewpoint Metamodel

The basic entities of engineering viewpoint metamodel and their interrelations as defined in the UML4ODP standard are illustrated in Figure 7. Most of the entities presented in the figure are briefly introduced in the following section. The metamodel is defined using standard UML notation.

Engineering Viewpoint UML Profile

In the UML4ODP engineering profile, an engineering object is expressed by a UML InstanceSpecification of component (e.g., an instance of component UML classifier), stereotyped as NV_Object. Basic engineering objects are particular kinds of engineering objects. Therefore, stereotype NV_BEO that identifies such objects inherits from NV_Object. A cluster is expressed by a UML InstanceSpecification of component, stereotyped as NV_Cluster. This includes a configuration of basic engineering objects and has bindings to required channels for communication. Likewise, cluster manager, capsule manager, nucleous, and node are expressed by a UML InstanceSpecification of component, stereotyped as NV_ClusterManager, NV_CapsuleManager, NV_Nucleus, and NV_Node, respectively. A channel is expressed by a UML package, stereotyped as NV_Channel. It consists of stubs, binders,
Frameworks for Model-Based Design of Enterprise Information Systems

protocol objects, and possibly interceptors. It is also expressed by a tag definition of Channel ID for a set of engineering objects (i.e., stub, binder, protocol object, and interceptor) comprising a channel. Also, a binder is expressed by a UML InstanceSpecification of component, stereotyped as NV_Binder. A diagrammatic representation of part of this UML profile is presented in Figure 8.

All the UML elements corresponding to the engineering language are defined within a UML model, stereotyped as Engineering_Spec. Such a model contains UML packages that express:

- Structure of a node, including nucleus, capsules, capsule managers, clusters, cluster managers, stubs, binders, protocol objects, interceptors, and basic engineering objects, with UML component diagram;
- Channels, with UML component diagram and packages;
- Domains, with UML packages; and
- Interactions among those engineering objects, with UML activity diagrams, state charts, and interaction diagrams.

The stereotype definition also comprises constraints expressed in object constraint language (OCL) (OMG, 2006). Examples of the constraints include:

- Each stub to which a basic engineering object is related must be part of a channel to which the BEO is related
  context BEO inv SameChannel: self.stub->forAll (stub | self.channel->exists (channel | channel = stub.channel))
- For each channel to which a basic engineering object is related, the basic engineering object must be related to exactly one stub that is part of that channel
  context BEO inv OneStubPerChannel: self.channel->forAll (channel | self.stub->select (stub | stub.channel = channel )->size () = 1 )

Figure 7. Part of the RM-ODP engineering viewpoint metamodel (ISO/IEC, 2006)
The basic engineering objects constituting a channel's endpoints must each reside in different clusters

**context** Channel  **inv** EndPointsInDifferentClusters:
self.endPoint ->forall (ep1, ep2 | ep1.cluster <> ep2.cluster)

As an example of the engineering specification, Figure 9 depicts the node structure of the enterprise server defined for the Templeman Library discussed in Annex B of ISO/IEC, 2006. As shown, in Figure 9, the enterprise server node consists of the node itself, nucleus, capsule, capsule manager, cluster, cluster manager, BEO(s), stub, binder, protocol object, and interceptor. In the enterprise server node configuration, BEOs for all computational objects are hosted in different clusters. The borrowing cluster is depicted in the figure. Communication is performed using stub1 (belonging in the channel connecting enterprise server to interaction server) and stub2 (belonging in the channel connecting enterprise server to enterprise information server).

The UML profiles of the five ODP viewpoints and corresponding metamodels have been defined using MagicDraw 10.0 and are available at www.rm-odp.net.

**Discussion**

It is self-evident that UML4ODP engineering specification fully corresponds to RM-ODP engineering language. It proposes a well-defined metamodel including all entities described in the RM-ODP engineering viewpoint. Based on this metamodel, a complete UML 2.0 profile is defined comprising a set of stereotypes, as well as a number of relative constraints written in OCL. The profile contributes to the wider acceptance and usage of RM-ODP, although it inherits all RM-ODP expression difficulties since it adopts the same terminology.

UML4ODP, as RM-ODP itself, is mainly focused on distributed application implementation based on the business requirements the applications should fulfill. However, performance requirements (e.g., expected response time for a certain application) are not considered. In particular, in the engineering viewpoint, allocation and replication decisions are not effectively explored, since the designer may relate engineering objects to nodes, but still has...
no means to explore the performance of alternative design decisions. Splitting the engineering view into two subviews, as suggested by Frankel (2003), might contribute towards this direction.

It is not within the scope of UML4ODP to define a formal methodology for EIS architecture design, though EIS architectures may be represented within engineering viewpoint specifications. Lastly, the integration of specific design tools (e.g., for resource allocation or performance evaluation) is also not mentioned.

**EIS DESIGN FRAMEWORK**

Like RUP SE and UML4ODP engineering viewpoint, EIS framework aims at augmenting the system analysis and design through model development. In particular, the framework provides:

1. A metamodel describing different views and the relations between them (EIS metamodel). These relations are strictly defined using constraints. The defined viewpoints provide the means to a) describe the network architecture, b) describe application logic in terms of the service requirements imposed to the network infrastructure, and c) perform resource allocation.

2. A methodology for EIS design based on the proposed views. The methodology consists of discrete stages performed by the system designer, software tools, or a combination of both. Taking advantage of the formal definition of relations identified between views, system design stages may be invoked as a result of metamodel constraint validation, ensuring that each stage can be independently performed.

3. A UML representation for all defined views. A UML 2.0 profile is defined for this purpose (EIS design profile).

The framework is based on three complementary viewpoints:

*Functional viewpoint* is used to describe functional specifications (e.g., system architecture, user behavior and application requirements). System architecture refers to the architectural model adopted. In the case of EIS, multitiered client-server models are described. Services provided by each applica-
tion tier (called modules) are also defined. User behavior is modeled through user profiles defining the behavior of different user groups and their performance requirements. Application requirements are described in terms of QoS requirements imposed to the network infrastructure (e.g., amount of data processed, transferred, or stored). Each service is described in a greater level of detail through the service description subview.

Topology viewpoint facilitates the definition of system access points and the resource allocation and replication. The term site is used to characterize any location (i.e., a building, an office, etc.). As such, a site is a composite entity which can be further analyzed into subsites, forming thus a hierarchical structure. Functional and topology views are interrelated. Resources (e.g., processes and files) correspond to services and data described through functional view and are located into sites.

Physical viewpoint refers to the aggregate network. Network nodes are either workstations allocated to users or server stations running server processes. Topology and physical views are interrelated. Both are decomposed to the same hierarchical levels of detail. At the lowest level, network nodes are related to processes/data replicas.

Figure 10 suggests a mapping of the proposed views to system model raw of Zachman’s matrix and RM-ODP engineering viewpoint (note that Frankel suggestion is adopted).

**EIS Metamodel**

Following, the metamodel will be analytically described in respect to each viewpoint.

**Functional Viewpoint**

For each distributed application operating in the EIS framework, a discrete functional view is defined. Applications are conceived as sets of interacting modules (either server or client), such as application servers, database servers, and so forth. Modules represent a coherent unit of functionality provided by a system. Each module offers specific services, representing the specific set of tasks executed when a module is activated in a certain way. Data entities are defined to indicate portions of data used by application modules. A file server module is used in each application for managing data entities. For each data entity, the name, size, and specific characteristics (whether it is executable or data, shareable, updatable, and replicable) must be defined.

User behavior is also described in functional view through user profiles activating client modules. Each profile includes user requests, which invoke specific client services. Each user request acquires a percentage attribute, indicating how often the user activates the specific application module, and a response time attribute indicating the time within which the request must be served.

For each module service, the requirements imposed to the distributed platform infrastructure must be defined. Thus, the portion of data processed, stored, or transferred must be estimated. Also other services participating in its implementation must be identified. This is performed using a set of predefined operations, sketching service functionality, and describing its needs for processing, storing, and transferring (called elementary operations) (Nikolaidou & Anagnostopoulos, 2005). Since it is difficult for the system designer to estimate the elementary operations describing service requirements, an operation library, named operation dictionary, is provided. Complex operations are added in the dictionary, such as request responsible for other service activation or write/read for data entity management. Complex operations represent the requirements of composite functionality. All complex operations are further decomposed into others, elementary or not. The system designer may add custom complex operations in the dictionary to ease the description of a specific application. Thus, a service description subview is defined for every service appearing in the functional view (see Figure 11).
Frameworks for Model-Based Design of Enterprise Information Systems

Physical Viewpoint

Physical view comprises the network infrastructure. The overall network is decomposed to subnetworks, producing thus a hierarchical structure. Local area networks (LANs) typically form the lowest level of the decomposition. Nodes, such as servers and workstations, are associated with LANs of the lowest level. Nodes may include a processing unit and a storage unit.

Topology Viewpoint

Topology view comprises sites, processes (defined as instances of application modules), data entity replicas (stored in the corresponding file server processes), and users (defined as instances of user profiles) (see Figure 11). Two types of sites are supported: composite, composed by others, and atomic, not further decomposed, constituting therefore the lowest level of site hierarchy. Users, processes, and data replicas are associated with atomic sites. In essence, the hierarchy indicates where (in which location) each process runs and each user is placed. The site hierarchy should correspond to the network hierarchy depicted in the physical view, while processes, files, and users are related to nodes included in physical view. Each site is characterized by QoS requirements as average and maximum network rate regarding process communication a) within site limits (avgWithin and maxWithin attributes of the site entity), b) exiting the site (avgOut and maxOut), and c) entering the site (avgIn and maxIn). These requirements must be satisfied by the throughput attribute of the corresponding network (see attributes of network entity in Figure 11). Thus, topology and physical views are interrelated. Both views can be either defined by the system designer or automatically composed by logical and physical configuration tools. The introduction of progressive site refinement, as well as the mapping of site range onto network range, enables the identification of dependencies between application configuration and network topology (Nikolaidou & Anagnostopoulos, 2005).

Consistency between these two views is accomplished using constraints embedded in the metamodel. Some of the constraints implementing the restrictions imposed between topology and physical views include:

- Network and site hierarchy must be identical, thus corresponding network and site entities must have corresponding parents. This constraint is used to initiate the respective logical or physical configuration tool, whenever the site or network hierarchy is changed.
- Topology view may only contain components (e.g., processes) related to entities (e.g., modules) belonging to existing functional views.
- Constraints are used to relate topology view entities (e.g., a server process) to the respective physical view entities (e.g., server node).
Frameworks for Model-Based Design of Enterprise Information Systems

Figure 11. The proposed EIS metamodel

It is obvious that the definition of constraints is a powerful mechanism to represent the dependencies between topology and physical view in a similar fashion for both the system designer and software tools addressing specific design issues.

**EIS Design Methodology**

EIS design framework facilitates the following discrete stages of system design process:

1. System requirement definition
2. Resource (process/data) allocation and replication policy definition
3. Network architecture design
4. Performance evaluation of the proposed solution (prior to implementation); although it is not a necessity, it is certainly useful

As resource allocation and network design problems cannot be independently solved, stages (2) and (3) are repeatedly invoked for different abstraction levels until an acceptable solution is reached (Nikolaidou & Anagnostopoulos, 2005). Both resource allocation and network architecture problems are usually supported by automated or semiautomated tools using mathematics, heuristics, or a combination of both. These tools may be repeatedly invoked for different abstraction levels (Graupner et al., 2001, Nezlek et al., 1999). The system designer may perform or partially perform these tasks on the system designer’s own time, thus both options must be supported. To evaluate system performance, a simulation tool as the one described by Nikolaidou and Anagnostopoulos (2003) can be used. The simulator uses as input the overall system model and produces performance results. Since each of these tools supports its own representation metamodel (e.g., queuing networks, Petri-nets, and objects), there is a need to properly create and instantiate the “internal” system model prior to invoking the tool. In order to facilitate
model exchangeability, the common metamodel is realized in XML, which is a standard exchangeable format. The partial transformation of the common metamodel into tool-specific metamodel must be facilitated before using an existing tool for a specific configuration stage.

The proposed methodology stages along with the EIS model consisting of the predefined views are presented in Figure 12. Discrete stages receive/modify information from/to specific system views, as depicted by the arrows between them. The relation between views and between stages is also depicted in the figure. Requirement definition is the initial stage and corresponds to the definition of system architecture and application requirements (functional view), the system access points (topology view), and existing network architecture, if any (physical view). A metamodel is provided for the formal definition of views and the relations between them. Each view is represented by one or more UML diagrams properly extended, thus a corresponding UML 2.0 profile is defined. Relations between views must also be described in the UML profile. Specific tool invocation and coordination must also be facilitated either by the profile or the metamodel itself or by both.

The metamodel itself contains relationships and restrictions inflicted between system entities belonging to the same or different views, which may lead to a specific stage invocation (e.g., if the network hierarchy in the physical view is modified, this modification must be depicted in the topology view as well). Embedding restrictions within the metamodel facilitates EIS design process management, taking into account the overall system model and not a specific system view corresponding to a discrete stage. Thus, the overall process becomes more effective, since discrete stage (and corresponding tool) dependencies are depicted within the model as view dependencies and consequently they are easily identified. Furthermore, it becomes more efficient to integrate autonomous software tools at different levels of detail, as each of them is independently invoked without knowing the existence of others.

**EIS Design UML 2.0 Profile**

In order to provide a standard method to represent system views and help the designer to efficiently interact with them, a UML 2.0 profile was defined facilitating the following:

1. Representation of EIS metamodel different views. More than one UML 2.0 diagram may be used for each view. Thus a specific system entity may participate in more than one diagram represented through a different UML entity.
2. Linkage between different model views, as represented in the metamodel.
3. Representation of all relationships and restrictions included in the metamodel. This must be applied between entities participating in the same or different UML diagrams to ensure model consistency.
4. Definition of system entities, attributes, and relationships.

UML 2.0 diagrams are used for the representation of different EIS views. The relative EIS entities are depicted as UML elements, properly extended to include additional properties and constraints. This means that appropriate UML 2.0 stereotypes have been defined for each view. Essentially, the concepts of the metamodel are reflected onto the stereotype attributes and constraints. Attributes convey the information required to describe EIS metamodel entities (e.g., throughput, activationFrequency, processingPower, etc.). Constraints, which are extensively used within the profile, represent relationships and restrictions between metamodel entities maintaining model consistency. Constraints mainly facilitate:

- Automatic computation of specific attribute values;
- Limiting attribute value range;
- Relating attribute values of specific elements to attribute values of other entities belonging
to the same or other UML diagrams (implementing thus the linkage between different models); and

- Model validation in view and overall model level.

Attributes and constraints for each stereotype are analytically introduced by Nikolaidou et al. (2006). Following, the UML diagrams employed for each view are briefly presented. Each stereotype has been named so that the first part of the name indicates the corresponding EIS metamodel entity, while the second part denotes the UML class it derives from.

**Functional View**

Functional views are represented as UML component diagrams, since the latter are eligible for representing system functionality at a logical level. As such, modules are defined as stereotypes of the UML component element (ServerModuleComponent and ClientModuleComponent). Module services are also defined as stereotypes of component (ServiceComponent stereotype) because in UML, a component has recursive properties, meaning that it may include other components. For the interactions among services, the InvokeDependency stereotype has been defined. Dependency is the relationship defined in UML between components. FileServerModuleComponent is the stereotype defined for the representation of a file server, which is associated with DataEntityComponent stereotypes used to depict data.

The UserProfileComponent stereotype has been defined for the representation of user profiles. Each profile may initiate client module services. Therefore, we have defined the InitiateDependency stereotype as a specialization again of UML dependency. As mentioned earlier, the interaction between user profiles and services plays a determinative role in system design, since user profiles

---

*Figure 12. EIS design framework*
Frameworks for Model-Based Design of Enterprise Information Systems

include performance requirements imposed by users. This is indicated by attributes of the User-ProfileComponent and InitiateDependency stereotypes. ActivationProbability attribute, for example, denotes how often a service is initiated while the user profile is active. Percentage attribute of the InitiateDependency stereotype indicates how often a specific service is activated by the user profile, while responseTime denotes the time constraints imposed to the execution of the service in respect to the user profile.

Concerning service implementation, it is represented through an activity diagram (ServiceImplementationActivity stereotype), as it involves flow of operations. Consequently, each ServiceImplementationActivity maps to a ServiceComponent. Thus, these two stereotypes have the same attributes. As already mentioned, service implementation consists of a sequence of operation activations executed upon module activation. Operations are represented through the OperationAction stereotype. The operation dictionary that includes the operations is represented through communication diagrams as the latter are used to show interactions among elements.

Figure 13 presents a simple application as an example. A user (student) initiates a simple search in a library Online Public Access Catalog (OPAC), thus performing a database search through the appropriate Common Gateway Interface (CGI) in the Web server. The example involves three modules: Web client, Web server, and External database server, consisting of services. The Web server module, for example, includes two services, get page and perform search. Figure 13 illustrates also the implementation of the simple search service as well as a fraction of the operation dictionary as the latter are used to show interactions among elements.

Figure 14a illustrates part of the University of Athens Library network.

Physical View

UML deployment diagrams are typically used to represent network architectures (Kaehkipuro, 2001). As such, the elements that denote devices are represented through stereotypes of device (i.e., ServerDevice, WorkstationDevice, ProcessUnitDevice, and StorageUnitDevice stereotypes), which is a specialization of the UML node element, commonly used in deployment diagrams.

As each network comprises subnetworks, the most suitable UML element for its representation is the package element, which is used for grouping purposes. Thus, we have created the NetworkPackage stereotype from the UML package element. These stereotypes may be connected to each other through the membership relation introduced in UML 2.0. Its notation is presented in the example of Figure 14a. This example illustrates part of the University of Athens Library network.

Topology View

Topology view is based on UML component diagrams. All entities included in topology view are represented through the corresponding stereotypes of component (i.e., ServerProcessComponent, ClientProcessComponent, and UserProfileComponent stereotype). Data replicas are also represented through a stereotype of component (i.e., DataReplicaComponent stereotype). Since each site comprises subsites, the most suitable UML element for its representation is the package element (as with network in physical view) Therefore, we have defined the stereotype SitePackage as a specialization of package. Interaction among process instances, as well as between user profile and client process instances, are represented through the InvokeDependency and InitiateDependency stereotypes respectively, with different constraints though, defined within the context of topology view. Sites relate to each other through the membership relationship. The topology view corresponding to the physical view of Figure 14a is presented in the Figure 14b.
As already stated, constraints are defined for the representation of relationships and restrictions between physical and topology views of the EIS metamodel and for the definition of interrelations between the corresponding stereotypes. An excerpt of the constraints defined in both views to ensure the consistency between them is included in Table 4.

Constraints 3-5 of the network package and 3-4 of site package ensure that site hierarchy of the topology view should correspond to the network hierarchy depicted in the physical view. Composite sites correspond to composite networks, while atomic sites correspond to atomic networks representing simple LANS. \(\text{Max}\) and \(\text{avg netReq}\) attributes of site package are automatically computed based on traffic flow within, in, and out of the site (constraint 5 in topology view). Instances of processes/user profiles (constraints 6-11 in physical view and constraint 9 in topology view) and data replicas (constraint 12 in physical views and 13 in topology view) located in atomic sites are allocated to nodes (servers or workstations) and storage devices included in the corresponding LAN of physical view. Note that constraints, as for example, those relating data replicas to storage devices, are applied in both views to avoid inconsistencies. Constraints are checked every time the system designer makes a change in either topology or physical view or a design tool is invoked. Changes may be either prohibited or propagated.

The proposed UML 2.0 profile has been implemented in rational software modeler in the form of a plug-in (EIS plug-in). EIS plug-in, apart from the definition of the stereotypes and constraints, also provides additional functionality that first augments usability for the system designer and second performs validation of the constraints defined within as well as between viewpoints. Through this plug-in,
Discussion

In the EIS design framework, a small number of viewpoints is proposed. The viewpoints as well as their interrelationships are formally defined through a metamodel. Based on this metamodel, consistency between views is ensured through the definition of constraints relating model entities belonging to the same (view consistency) or different (inter-view consistency) views. The small number of views enables their effective manipulation.

EIS framework strictly focuses on system design issues, such as resource allocation and architecture specification. The function column of Zachman’s matrix is regarded as the initial view the system designer should consider, corresponding to system architecture and functionality (functional viewpoint). Data and people columns do not fall into the scope of EIS design framework as the latter deals only with data allocation and replication policies rather than data specification, while user profiles are used mainly to indicate user behavior and performance requirements affecting system modules. All views are supported by UML 2.0 stereotypes, typically defined in a UML profile. Constraints are used extensively to maintain consistency and depict all the relations defined between system entities included in the metamodel.

The methodology proposed addresses all issues related to EIS design, utilizing the viewpoints defined, through four discrete stages (i.e., requirement definition, resource allocation, network design, and

Figure 14. (a) Physical view example (b) topology view example
Frameworks for Model-Based Design of Enterprise Information Systems

The last three stages may be performed by the system designer or specialized tools. Moreover, EIS framework supports model exchangeability through the transformation of the common metamodel to internal tool-specific metamodels.

FUTURE TRENDS

Model-based system design is based on the assumption that a central system model can be defined, covering all aspects related to system analysis and design, in a similar fashion as the platform-independent model serves model-based software engineering. In both cases, UML is the dominating choice for representation purposes. An important issue though is the provision of an integrated model for both software and system design. There are already endeavors initiated, such as RUP framework, working towards this direction. It is important that not only common principles are introduced, but also a formal identification and definition of model dependencies and transformations is established.

Agile systems, as described by Dove (2005), are imperative for modern enterprises operating in highly turbulent environments, since such systems are able to adjust to both expected and unpredicted performance evaluation).
Frameworks for Model-Based Design of Enterprise Information Systems

changes in a timely and cost-effective manner. Model-driven architectures, such as MDA, are working towards obtaining system agility, which can be strengthened by a common model-based approach to study all aspects regarding enterprise information system design and development. Existing enterprise architecture frameworks, such as those presented in this chapter, should be enhanced to serve agility.

CONCLUSION

This chapter discussed the model-driven design of enterprise information systems and the principle requirements for applying it to EIS analysis and design.

Three different frameworks, namely RUP SE, UML4ODP, and EIS design framework, were studied in respect to these requirements. The frameworks have different origin, and they target different system design aspects. However, they all adopt UML language for model representation and contribute to the system analysis and design process. The characteristics of each framework in respect to the system design requirements identified in the previous section are summarized in Table 5.

Frameworks for Model-Based Design of Enterprise Information Systems

KEY TERMS

Central System Model: A technology-neutral multilevel model used as a basis for model-based system design.

Model-Based EIS Design Requirements: Requirements that EIS analysis and design frameworks must satisfy to effectively facilitate model-based system design.

Model-Based System Design: A system design method providing a central system model (tool-independent) that captures system requirements and design decisions that fulfill them at different levels of abstraction. It enables integration of system models supported by autonomous design tools and interoperability between them without interfering with their internal implementation.

System Design: The process of analyzing system requirements, designing the desired architecture of a system, and exploring performance requirements, ensuring, thus, that all system components are identified and properly allocated and that system resources can provide the desired performance.

System Engineering: The interdisciplinary approach and means to enable the realization of successful systems.

System Model: A set of entities and their relationships describing a system.

System Model Representation: A graphical notation for the illustration of a system model.

View: A representation of the whole system from the perspective of a related set of concerns.

Viewpoint: The perspective from which a view is taken. It serves a specific category of system stakeholders.
